## Abstract

**Keywords:** Bayesian inference, DNA barcoding, intraspecific genetic distance, interspecific genetic distance, specimen identification, species discovery, Stan

## 1 Introduction

Since its inception over 20 years ago, DNA barcoding (Hebert et al., 2003a,b) has emerged as a robust method of specimen identification and species delimitation across myriad taxonomic groups which have been sequenced at short, standardized gene regions like 5'-COI for animals. However, the success of the approach depends crucially on two important factors: (1) the availability of high-quality specimen records found in public reference sequence databases such as the Barcode of Life Data Systems (BOLD) Ratnasingham and Hebert (2007), and (2) the establishment of a DNA barcode gap — the idea that the maximum genetic distance observed within species is much smaller than the minimum degree of marker variation found among species (Meyer and Paulay, 2005; Meier et al., 2008). Early work has demonstrated that the presence of a DNA barcode gap hinges strongly on extant levels of species haplotype diversity gauged from comprehensive specimen sampling at wide geographic and ecological scales. Despite this, many taxa lack adequate separation in their pairwise intraspecific and interspecific genetic distances, thereby compromising rapid matching of unknown samples to expertly-validated references.

Recent work has argued that DNA barcoding, in its current form, is lacking in statistical rigor, calling into question the existence of a true species' DNA barcode gap Phillips et al. (2022). To support this notion, novel nonparametric locus-specific metrics based on the multispecies coalescent (Rannala and Yang, 2003; Yang and Rannala, 2017) were recently outlined and shown to hold strong promise when applied to *Agabus* diving beetles Phillips et al. (2024). The metrics quantify the extent of asymmetric directionality of proportional

genetic distance distribution overlap/separation for species within well-sampled genera based on a straightforward distance count. Values of the metrics close to zero suggest the existence of DNA barcode gaps, whereas values near one lend credence for the absence of gaps. However, what appears to be missing is an unbiased way to compute the statistical accuracy of the recommended estimators arising through problems inherent in frequentist maximum likelihood estimation for discrete probability distributions having bounded support. To this end, here, a Bayesian model of the DNA barcode gap coalescent is introduced to rectify such issues. The model allows accurate estimation of posterior means, posterior standard deviations, posterior quantiles, and credible intervals for the metrics given datasets of intraspecific and interspecific genetic distances for species of interest.

## 2 Methods

### 2.1 DNA Barcode Gap Metrics

Recently, Phillips et al. (2024) proposed novel nonparametric maximum likelihood estimators (MLEs) of proportional overlap/separation between intraspecific and interspecific pairwise genetic distance distributions for a given species ( $x$ ) to aid assessment of the DNA barcode gap as follows:

$$p_x = \frac{\#\{d_{ij} \geq \min(d_{XY})\}}{\#\{d_{ij}\}} \quad (1)$$

$$q_x = \frac{\#\{d_{XY} \leq \max(d_{ij})\}}{\#\{d_{XY}\}} \quad (2)$$

where  $d_{ij}$  and  $d_{XY}$  are distances within and among species, respectively, and the notation  $\#$  reflects a count. Distances are easily computed from a model of DNA sequence evolution, such as  $p$  distance. Similar expressions (denoted  $p'_x$  and  $q'_x$ ) for nearest neighbour species were also given (see Phillips et al. (2024)), in which  $d_{XY}$  included only interspecific distances

between the species of interest and its closest neighbouring species. If a focal species is found to have multiple nearest neighbours, then the species possessing the smallest average pairwise interspecific distance is used. While these schemes differ considerably from the usual definition of the DNA barcode gap laid out by Meyer and Paulay (2005) and Meier et al. (2008), they more accurately account for species' coalescence histories inferred from contemporaneous DNA sequences. such as interspecific hybridization/introgression events (Phillips et al., 2024). Note, distances (and hence the metrics) are constrained to the closed interval  $[0, 1]$ . Values of the estimators obtained from equations (1) and (2) close to or equal to zero give evidence for separation between intraspecific and interspecific genetic distance distributions; that is, values suggest the presence of a DNA barcode gap. Conversely, values near or equal to one give evidence for distribution overlap; that is, values likely indicate the absence of a gap.

## 2.2 A Bayesian Implementation

A major criticism of large sample (frequentist) theory is that it relies on asymptotic properties of the MLE (which is assumed to be a fixed but unknown quantity), such as estimator normality and consistency. This problem is especially pronounced in the case of binomial proportions. The estimated Wald SE of the sample proportion, is given by

$$\widehat{SE}[\hat{p}] = \sqrt{\frac{\hat{p}(1 - \hat{p})}{n}}, \quad (3)$$

where  $\hat{p} = \frac{Y}{n}$  is the MLE,  $Y$  is the number of successes ( $Y = \sum_{i=1}^n y$ ) and  $n$  is the number of trials (*i.e.*, sample size). However, the above formula is problematic for several reasons. First, Equation (3) makes use of the Central Limit Theorem (CLT); thus, large sample sizes are required for reliable estimation. When few observations are available, SEs will be large and inaccurate, leading to low statistical power. Further, resulting interval estimates could span values less than zero or greater than one, or have zero width, which is practically meaningless. Second, when proportions are exactly equal to zero or one, resulting SEs will be exactly zero,

rendering Equation (3) completely useless. In the context of the proposed DNA barcode gap metrics, values obtained at the boundaries of their support are often encountered. Therefore, reliable calculation of SEs is not feasible. Given the importance of sufficient sampling of species genetic diversity for DNA barcoding initiatives, a different statistical estimation approach is necessary. Bayesian inference offers a natural path forward in this regard since it allows for direct specification of prior beliefs concerning unknown model parameters and permits the seamless propagation of uncertainty, when data is lacking, through integration with the likelihood function. As a consequence, Bayesian models are much more flexible and generally more easily interpretable compared to frequentist approaches since direct probability statements can be made.

## 2.3 The Model

Essentially, from a statistical perspective, the goal herein is to nonparametrically estimate extreme tail probabilities for positive highly skewed distributions on  $[0, 1]$ . This is a challenging problem as detailed in subsequent sections. Counts,  $y$ , of overlapping genetic distances (as expressed in the numerator of Equations (1) and (2)) are treated as binomially distributed with expectation  $\mathbb{E}[Y] = k\theta$ , where  $k = \{N, M, C\}$  are total counts of intraspecific, interspecific, and combined genetic distances for a target species, and  $\theta = \{p_x, q_x, p'_x, q'_x\}$ . The metrics encompassing  $\theta$  are presumed to follow a  $\text{beta}(\alpha, \beta)$  distribution, which is a natural choice of prior on probabilities. Such a scheme is quite convenient since the beta distribution is conjugate to the binomial distribution. Thus, the posterior distribution is also beta distributed. Parameters were given an uninformative  $\text{Beta}(1, 1)$  prior, which is equivalent to a standard uniform ( $\text{Uniform}(0, 1)$ ) prior since it places equal probability on all parameter values within its support. As a result, the posterior is  $\text{Beta}(Y + 1, n - Y + 1)$ , which has expected value  $\mathbb{E}[Y] = \frac{Y+1}{n+2}$  and variance  $\mathbb{V}[Y] = \frac{(Y+1)(n-Y+1)}{(n+2)^2(n+3)}$ . In general however, when possible, it is always advisable to incorporate prior information, even if only weak, rather than simply imposing complete

102 ignorance in the form of a flat prior distribution. The full univariate Bayesian model is thus  
 103 given by

$$\begin{aligned}
 y_{\text{lwr}} &\sim \text{Binomial}(N, p_{\text{lwr}}) \\
 y_{\text{upr}} &\sim \text{Binomial}(M, p_{\text{upr}}) \\
 y'_{\text{lwr}} &\sim \text{Binomial}(N, p'_{\text{lwr}}) \\
 y'_{\text{upr}} &\sim \text{Binomial}(C, p'_{\text{upr}}) \\
 p_{\text{lwr}}, p_{\text{upr}}, p'_{\text{lwr}}, p'_{\text{upr}} &\sim \text{Beta}(1, 1)
 \end{aligned} \tag{4}$$

104 given sufficient data, the choice of prior distribution becomes less important since the  
 105 posterior will be directly proportional to the likelihood.

106 The model was fitted using the Stan probabilistic programming language (Carpenter  
 107 et al., 2017) framework for Hamiltonian Monte Carlo (HMC) via the No-U-Turn Sampler  
 108 (NUTS) algorithm (Hoffman and Gelman, 2014) sampling through the `rstan` R package  
 109 (Stan Development Team, 2023). Four chains were run for 2000 iterations each in parallel  
 110 across four cores with random parameter initializations. Within each chain, a total of 1000  
 111 samples was discarded as warmup (*i.e.*, burnin) to reduce dependence on starting conditions.  
 112 Further, 1000 post-warmup draws were utilized per chain. Each of these reflect default  
 113 MCMC settings in Stan. Since the DNA barcode gap metrics often attain values very close  
 114 to zero and/or very near one, in addition to more intermediate values, a  $\text{Beta}(\frac{1}{2}, \frac{1}{2})$  prior,  
 115 which is U-shaped symmetric and places greater probability density at the extremes of the  
 116 distribution due to its heavier tails, while still allowing for variability in parameter estimates  
 117 within intermediate values along its domain, was also attempted. However, this resulted in  
 118 several divergent transitions, among other pathologies, imposed by complex geometry (*i.e.*,  
 119 curvature) in the posterior space, despite remedies to resolve them, such as lowering the step  
 120 size of the HMC sampler. Note that this prior is Jeffreys' prior, which is proportional to the

121 square root of the Fisher information and has several desirable statistical properties, most  
122 notably invariance to reparameterization.
