#### 7 Abstract

g

Since its inception over 20 years ago, DNA barcoding has emerged as a robust method of specimen identification and species delimitation across myriad taxonomic groups which have been sequenced at short, standardized gene regions like 5'-COI for animals. However, the success of the approach depends crucially on two important factors: (1) the availability of high-quality specimen records found in public reference sequence databases such as BOLD, and (2) the establishment of a DNA barcode gap — the idea that the maximum genetic distance observed within species is much smaller than the minimum degree of marker variation found among species. Early work has demonstrated that the presence of a DNA barcode gap hinges strongly on extant levels of species haplotype diversity gauged from comprehensive specimen sampling at wide geographic and ecological scales. Despite this, many taxa lack adequate separation in their pairwise intraspecific and interspecific genetic distances, thereby compromising rapid matching of unknown samples to expertly-validated references.

Recent work has argued that DNA barcoding, in its current form, is lacking in statistical rigor, calling into question the existence of a true species' DNA barcode gap. To support this notion, novel nonparametric locus-specific metrics based on the multispecies coalescent were recently outlined and shown to hold strong promise when applied to Agabus diving beetles. The metrics quantify the extent of asymmetric directionality of proportional genetic distance distribution overlap/separation for species within well-sampled genera based on a straightforward distance count. Values of the metrics close to zero suggest the existence of DNA barcode gaps, whereas values near one lend credence for the absence of gaps. However, what appears to be missing is an unbiased way to compute the statistical accuracy of the recommended estimators arising through problems inherent in frequentist maximum likelihood estimation for discrete probability distributions having bounded support. Here, a Bayesian model of the DNA barcode gap coalescent, written using the Stan software, is introduced to rectify such issues. The model allows accurate estimation of posterior means, posterior standard deviations, posterior quantiles, and credible intervals for the metrics given

#### 39 1 Introduction

DNA barcoding (Hebert et al., 2003a,b) was conceived more than two decades ago as an 40 immediate and automatic solution to the taxonomic impediment during a time of ongoing 41 biodiversity crisis. The technique promised the rapid and accurate identification of unknown specimens to known Linnaean binomens, as well as the unambiguous resolution of species 43 boundaries across the eukaryotic Tree of Life through the leveraging of easily obtained genetic variation found in short, universal segments of DNA. In animals, a c. 658 bp fragment from the 5' end of the mitochondrial cytochrome c oxidase subunit I gene is employed as a DNA barcode due to its ease of isolation, amplification, and sequencing. As a result, dedicated community-curated genomic sequence databases like the Barcode of Life Data Systems (BOLD) (Ratnasingham and Hebert, 2007) have accumulated appreciable levels of intraspecific genetic variation across a wide range of taxa and geographic regions to accelerate specimen identification and species discovery tasks essential to addressing novel research questions in ecology and evolutionary biology. Despite this,

## <sup>53</sup> 2 Methods

## 54 2.1 DNA Barcode Gap Metrics

Recently, Phillips et al. (2024) proposed novel nonparametric maximum likelihood estimators of proportional overlap/separation between intraspecific and interspecific pairwise genetic distance distributions for a given species (x) to aid assessment of the DNA barcode gap as follows:

$$p_{x} = \frac{\#\{d_{ij} \ge \min(d_{XY})\}}{\#\{d_{ij}\}}$$

$$q_{x} = \frac{\#\{d_{XY} \le \max(d_{ij})\}}{\#\{d_{XY}\}}$$

$$(2)$$

$$q_x = \frac{\#\{d_{XY} \le \max(d_{ij})\}}{\#\{d_{XY}\}}$$
 (2)

where  $d_{ij}$  and  $d_{XY}$  are distances within and among species, respectively, and the notation # reflects a count. Distances are easily computed from a model of DNA sequence evolution, 60 such as p distance. Similar expressions (denoted  $p'_x$  and  $q'_x$ ) for nearest neighbour species 61 were also given (see Phillips et al. (2024)), in which  $d_{XY}$  included only interspecific distances 62 between the species of interest and its closest neighbouring species. If a focal species is 63 found to have multiple nearest neighbours, then the species possessing the smallest average 64 pairwise interspecific distance is used. While these schemes differ considerably from the 65 usual definition of the DNA barcode gap laid out by Meyer and Paulay (2005) and Meier 66 et al. (2008), they more accurately account for species' coalescence histories inferred from 67 contemporaneous DNA sequences. such as hybridization/introgression events (Phillips et al., 68 2024). Note, distances (and hence the metrics) are constrained to the closed interval [0, 1]. Values of the estimators obtained from equations (1) and (2) close to or equal to zero give evidence for separation between intraspecIfic and interspecific genetic distance distributions; 71 that is, values suggest the presence of a DNA barcode gap. Conversely, values near or equal to one give evidence for distribution overlap; that is, values likely indicate the absence of a gap.

#### 2.2A Bayesian Implementation

A major criticism of large sample (frequentist) theory is that it relies on asymptotic 76 properties of the MLE (which is assumed to be fixed but unknown), such as normality. This 77 problem is especially pronounced in the case of binomial proportions. The estimated Wald 78 SE of the sample proportion, is given by

$$\widehat{SE[\hat{p}]} = \sqrt{\frac{\hat{p}(1-\hat{p})}{n}},\tag{3}$$

where  $\hat{p} = \frac{X}{n}$  is the MLE, X is the number of sucesses, and n is the number of trials. However, the above formula is problematic for several reasons. First, Equation (3) makes 81 use of the Central Limit Theorem (CLT); thus, large sample sizes are required for reliable estimation. When few observations are available, SEs will be large and inaccurate, leading to low statistical power. Further, resulting interval estimates could span values less than zero or greater than one, or have zero width, which is practically meaningless. Second, when 85 proportions are exactly equal to zero or one, resulting SEs will be exactly zero, rendering 86 Equation (3) completely uselesss. In the context of the proposed DNA barcode gap metrics, 87 values obtained at the boundaries of their support are often encountered. Therefore, reliable 88 calculation of SEs is not feasible. Given the importance of sufficient sampling of species 89 genetic diversity for DNA barcoding initiatives, a different statistical estimation approach is 90 necessary. Bayesian inference offers a natural path forward in this regard. 91

#### $_{92}$ 2.3 The Model

101

Counts, Y, of overlapping genetic distances (as expressed in the numerator of Equations (1) and (2)) are treated as binomially distributed with expectation  $\mathbb{E}[Y] = k\theta$ , where  $k = \{N, M, C\}$  are total counts of intraspecific, interspecific, and combined genetic distances for a target species, and  $\theta = \{p_x, q_x, p_x', q_x'\}$ . Although the metrics encompassing  $\theta$  are presumed to follow a beta distribution, for simplicity, the metrics are given standard uniform (U(0,1)) priors, which is mathematically equivalent to a Beta(1, 1) distribution. Such a scheme is mathematically convenient since the beta distribution is conjugate to the binomial distribution. Thus, the posterior distribution is also beta distributed.

Thus, the full Bayesian model is given by
